Some identity must hold write on the command topic, or the alarm cannot be commanded at all.
Which identity the adversary steals is what decides the outcome.

PER-CLIENT ACL — modelled, and reproduced on Mosquitto 2.0.18

identity	cmd topic: publish	cmd topic: subscribe	stat topic: publish
controller	**allow**	deny	deny
device	deny	**allow**	**allow**

Only the controller may publish commands; the device may only read them. (Broker usernames: operator, device.)

Which compromise each control contains

Device credential stolen

ACL holds

the device identity has no write on the command topic, so the broker refuses the publish

Controller credential stolen

ACL fails

that identity is the one the ACL must authorise to publish commands

One shared credential stolen

ACL fails

it must carry write on the command topic, so the configuration collapses to no ACL

The ACL and the MAC fail under different compromises

The command key and the device's broker credentials share one flash image, so a flash dump yields both; the ACL still refuses that identity, and the layered build holds. A compromised controller host is the opposite case: it yields a credential the ACL must permit and the key to sign with, so neither layer refuses it.
